Therefore, at no load, the current in the motor is determined by  $R_1$  and  $X_1$  in series with the magnetizing circuit,  $G_c$  and  $X_m$ . As the motor is loaded, the slip increases and  $R_2/s$  decreases causing the motor to draw more current. The diagram represents one phase of a three-phase induction motor.

Where you see a crystal specifying a load capacitance, it is generally expected that you would use it in a parallel-resonant circuit, where crystal impedance rises to a maximum, and voltage across its terminals peaks at the desired operating frequency. The operating frequency can be adjusted by varying the external parallel capacitance  $C_p$ .

The setting simply selects what load impedance you have so that the display reads the voltage you get at the load. For example if the unloaded output is 2Vpp, it will be 1Vpp when you connect a 50 ohm load, because the generator has a 50 ohm output impedance.

The downward trend is a bit like load cell creep, but the amount seems large (though perhaps not for a \$4 load cell- 10 grams is only 0.2% of full scale) perhaps try replacing the load cells with similar valued precision resistors to determine the source of the drift.

Shifting for at least 20% load can reduce consumer's monthly electricity bills by approximately 0.7% compared to flat-rate tariffs. For utilities, the implementation of dynamic pricing can potentially increase monthly revenue by up to 21%.

this CC load. For example, discharging a 10AH 12V battery vs a 500AH 12V battery in say an hour could produce power dissipation levels in the 100W to 6kW range. How do you control starting and stopping (turning off and on) this CC load.
